#### Project — Part I (Analytical Option Formulae)

Consider the following European options:

- Vanilla call/put
- Digital cash-or-nothing call/put
- Digital asset-or-nothing call/put

Derive and implement the following models to value these options in Python:

- Black-Scholes model
- 2 Bachelier model
- 3 Black76 model
- 4 Displaced-diffusion model

# Project — Part II (Model Calibration)

On 30-Aug-2013, Google stock price was \$846.9. The call and put option prices (bid & offer) are provided in the spreadsheet

- goog\_call.csv
- goog\_put.csv

The discount rate on this day is in the file: discount.csv.

Calibrate the following models to match the option prices:

- 1 Displaced-diffusion model
- **2** SABR model (fix  $\beta = 0.8$ )

Plot the fitted implied volatility smile against the market data.

Report the model parameters:

- $\bullet$   $\sigma$ ,  $\beta$
- $\mathbf{2}$   $\alpha$ ,  $\rho$ ,  $\nu$

And discuss how does change  $\beta$  in the displaced-diffusion model and  $\rho$ ,  $\nu$  in the SABR model affect the shape of the implied volatility smile.

2/6

#### Project — Part III (Static Replication)

Suppose on 30-Aug-2013, we need to evaluate European derivatives expiring on 17-Jan-2015 and paying:

1 Payoff function:

$$S_T^3 + 2.5 \times \log(S_T) + 10.0$$

2 "Model-free" integrated variance:

$$\sigma_{\mathsf{MF}}^2 T = \mathbb{E}\left[\int_0^T \sigma_t^2 \ dt\right]$$

Determine the price of these 2 derivative contracts if we use:

- **1** Black-Scholes model (what  $\sigma$  should we use?)
- **2** Bachelier model (what  $\sigma$  should we use?)
- Static-replication of European payoff (using the SABR model calibrated in the previous question)

## Project — Part IV (Dynamic Hedging)

Suppose  $S_0=\$100$ ,  $\sigma=0.2$ , r=5%,  $T=\frac{1}{12}$  year, i.e. 1 month, and K=\$100. Use a Black-Scholes model to simulate the stock price. Suppose we sell this at-the-money call option, and we hedge N times during the life of the call option. Assume there are 21 trading days over the month.

The dynamic hedging strategy for an option is

$$C_t = \phi_t S_t - \psi_t B_t,$$

where

$$\phi_t = \frac{\partial C}{\partial S} = \Phi\left(\frac{\log\left(\frac{S_t}{K}\right) + \left(r + \frac{1}{2}\sigma^2\right)(T - t)}{\sigma\sqrt{T - t}}\right),\,$$

and

$$\psi_t B_t = -K e^{-r(T-t)} \Phi\left(\frac{\log\left(\frac{S_t}{K}\right) + \left(r - \frac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}\right).$$

## Project — Part IV (Dynamic Hedging)

The final P&L of our dynamic hedging strategy, i.e. the hedging error, is defined as

Hedging Error = 
$$\left(\phi_T S_T - \psi_T B_T\right) - \max\{S_T - K, 0\}.$$

Use 50,000 path in your simulation, and plot the histogram of the hedging error for N=21 and N=84.
